ABSTRACT

Development of Northern Great Plains coal resources will create new demands for state and local government services. Development will also produce increased government revenues. Special taxes on coal production have been enacted in Hontana, North Dakota, and Wyoming in order to ensure that state and local governments receive sufficient revenues to finance the new services required. This study reports detailed estimates of the state and local taxes that would be paid by three different-sized coal mines and their employees in Montana, North Dakota, Scuth Dakota, and Wyoming. The estimates were obtained by using the EMERGYTAX simulation model. While in all states the total revenue available appears sufficient to meet the increased demands for services attributable to the mines, there are other considerations. When the analysis is done by type of government, state governments and, to a lesser extent, county governments appear to receive enough new revenues to meet their needs. The cities and, in some states, the school districts appear less well-off. State and local governments may also face a cash flow problem when mineral development occurs. (Author/IRT)

ABSTRACT

Development of Northern Great Plains coal resources will create new demands for State and local government services. Development will also produce increased government revenues. Special taxes on coal production have been enacted in Montana, North Dakota, and Wyoming in order to insure that State and local governments receive sufficient revenues to finance the new services required. This study reports detailed estimates of the State and local taxes that would be paid by three different sized coal mines and their employees in Montana, North Dakota, South Dakota, and Wyoming. The estimates were obtained by using the ENERGYTAX simulation model.

Keywords: Taxation, Model, Economic development, Economic impact, Public finance, Public revenues

This study was conducted by the Economic Development Division of the Economics, Statistics, and Cooperatives Service, U.S. Department of Agriculture, in cooperation with the University of Minnesota and North Dakota State University through support of the Office of Research and Development, U.S. Environmental Protection Agency (Contract EPA-1AG-D6-E766). Thomas F. Stinson is stationed at the University of Minnesota and Stanley W. Voelker is located at the North Dakota State University. Both are members of the Economics, Statistics, and Cooperatives Service.

On January 1, 1978, three USDA agencies—the Economic Research Service, the Statistical Reporting Service, and the Farmer Cooperative Service—merged into a new organization, the Economics, Statistics, and Cooperatives Service.

Development of coal resources in the Northern Great Plains need not create major financial problems for State and local governments. But while total State-local revenues will be adequate, some levels of governments, such as cities, may face serious revenue shortfalls when they provide additional services. Others, particularly the States, will have a surplus. These estimates are based on coal mines typical of those which might locate in Montana, North Dakota, South Dakota, and Wyoming, and on 1976 tax laws in those States. The estimates were obtained by using the ENERGYTAX simulation model.

Cities face particularly serious financial problems, with potential expenditures for increased services outpacing new revenues by more than 2 to 1 School districts which receive large numbers of new students but do not have mine property within their boundaries will have similar problems. The special coal impact funds established in Montana, North Dakota, and Wyoming could reduce these financial difficulties, however.

State and local governments in Montana would receive the most revenue from coal development; those in South Dakota the least. In Montana, both the 9.2-and the 5-million-ton-per-year mines would generate more than \$55,000 annually per new employee directly employed by the mine. The same mines located in North Dakota and Wyoming would produce more than \$18,000 per new employee. In South Dakota, where there is no special coal tax, the mines would produce only about \$4,700 per year.

While in all States the total revenue available appears sufficient to meet the increased demands for services attributable to the mines, there are other considerations. First, government services are provided by several types of governments, each with their own sources of revenue. A significant financial problem for one or more levels of government could be hidden by a surplus at other levels. When the analysis is done by type of government, State governments, and to a lesser extent county governments, appear to receive enough new revenues to meet their needs. The cities, and in some States the school districts, appear less well off.

State and local governments may also face a cash flow problem when mineral development occurs. During the mine's construction and development phase, and during the period when the mine is being closed down, local governments will be required to provide services for the mine's employees at a time when tax revenues from the mine are minimal. Taxing at a rate somewhat higher than necessary during the operating years of the mine in order to provide the funds necessary for services during the low revenue years is one way the front end and closedown problems can be minimized.

Finally, mines may inflict other social costs on the residents of a State or region. Increased taxes on the mines and decreased taxes on individuals can partially compensate for these costs.

ACKNOWLEDGMENTS

Construction of the tax models for Montana and Wyoming would have been impossible without the assistance of Layton S. Thompson, Montana State University, who collected detailed information about the tax systems of those States. Kweiwu Fang, University of Minnesota, assisted with the programming of the models and made important contributions to their structure. Lloyd Bender, ESCS-Montana, provided considerable assistance and encouragement throughout the study.

The entire project was made much easier by the cooperation of many State and local tax officials in the Northern Great Plains. Their willingness to review the model and indicate potential problem areas is greatly appreciated.

The study also benefited from helpful critiques by other members of the research team: Fred K. Hines, Jerome M. Spam, Andrea J. Lubov, Jeff V. Conopask, Paul R. Myers, and George Temple. The initial development of the model was partially supported by a grant from the University Computing Center, University of Minnesota.

COAL DEVELOPMENT IN THE NORTHERN GREAT PLAINS.
The Impact on Revenues of State and Local Governments

Thomas F. Stinson Stanley W. Voelker

INTRODUCTION

The Nation's energy program places increased emphasis on the development and use of coal. Increasing production by more than two-thirds, to over 1 billion tons per year by 1985, is now a national goal. And, a number of measures designed to encourage major energy users to substitute coal for oil and natural gas have been proposed to Congress.

Much of the increased coal production is expected to take place in the Northern Great Plains States of Montana, North Dakota, and Wyoming. Of the additional 546 million tons of annual production identified as possible or planned fee the United States by 1985, 243 million tons are expected to come from that area. 1/ The region's thick seams of low sulfur coal are extremely attractive to energy developers because of the relatively low cost of mining. Until the more exotic sources of power -- wind, solar, and geothermal to become economically efficient, coal exports from these States will steadily increase.

Development of Northern Great Plains coal will have a major impact on the region. Many are concerned about possible adverse effects on the quality of life in the area. Environmental groups fear that reclamation will prove to be impossible or that the States will not enforce sufficiently high reclamation standards. Others worry about the impact of relatively large population increases in these sparsely populated areas. Special concern has been voiced about the effects population growth will have on the community's ability to finance and deliver essential local government services such as education and police and fire protection. Because revenues produced by development may not increase as rapidly as the demand for services, local residents could see both a decline in their quality of life and an increase in their property tax bill. All these concerns, combined with a general feeling that minerals belong to the State and that the people of the State should receive some compensation for their use, have led to pressure for higher State taxes on coal production.

Now, as the rest of the Nation faces higher utility bills. State coal taxes are under fire. A national research organization has characterized the existing State tax situation for western coal as being the same as "OPEC like revenue maximization."2/ The same report hoted that, "If the states do not exercise

^{1/} Office of Coal, Federal Energy Administration, 1 Mine Expansion Study, May 1976, p. 19.

^{2/} Richard Nehring and Benjamin Zycher with Joseph Wharton, Coal Development and Government Regulation in the Northern Great Plains: A+Preliminary Report, R-1981-NSF/RC, Rand Corp., Santa Monica, Calif., Aug. 1976, p. 148.

restraint in applying their taxing powers, the federal government may wish to set limits on the level of special taxes on energy production."3/ Clearly, some believe that taxes on coal production are excessive.

This study, focusing on the taxation issue, reports the results obtained when a computer simulation model (ENERGYTAX) was applied to data describing three model mines typical of the size of development likely to occur. Estimates of the revenue accruing from each model mine and its employees for each major tax levied at each level of government are presented for Montana, North Dakota, South Dakota, and Wyoming. In addition, estimates of the intergovernmental revenues directly attributable to coal development are given. The report describing the tax simulation models and the model mines, discusses the simulation results and notes what can and cannot be concluded.

This study is only a first step in estimating the net fiscal impacts of new coal development on State and Tocal governments in the Northern Great Plains. Only direct revenue impacts are reported. No attempt is made to estimate revenues derived from the secondary or ancillary development which may accompany the mine, nor is any attempt made to estimate the costs associated with providing the government services required by new workers. While average per capita expenditures are provided for comparison purposes, they are only general guidelines. They should not be used to estimate the additional public sector costs associated with a project. Studies are currently underway to develop improved methodologies for estimating secondary revenues and public sector costs. The results obtained using a more complete model will be the subject of a later report.

THE ENERGYTAX MODEL

ENERGYTAX, a simulation model developed by the Economic Research Service, was used to produce the revenue estimates presented in this report. ENERGYTAX is actually a family of four separate models, each of which is similar in its basic structure. Each model, however, includes parameters which reflect the tax system and intergovernmental aid structure of a particular State. At present, States for which revenue impacts of coal development can be simulated are Montana, North Dakota, South Dakota, and Wyoming.

The simulation models estimate taxes paid and revenue flows for any coal-related energy development. Export mines, thermogenerators, and gasification plants in any combination can be included with no modification of the model. All that is required is that the user provide the necessary information about the size of the development, its work force, and the estimated values of production and equipment. (A more complete description of the input data required by the model is given in Appendix A.) Given these input data, ENERGYTAX will generate reliable estimates of the State and local taxes paid by the mine or coal conversion plant and its employees. The accuracy of these estimates depends in large part on the accuracy of the data provided by the user.

ENERGYTAX is more closely related to accounting models than to large-scale economic forecasting models. The program is a series of accounting identities

^{3/} Ibid., p. 100.

through which tax payments by source and flows of intergovernmental aid can be computed. Values for different types of taxable property are read into the program and the appropriate tax rates are applied to compute taxes paid. As part of the model, changes in the characteristics of the local community (such as number of school-age children and the total number of residents) and changes in the tax base associated with the new development are calculated, and then inserted into the proper State aid formula to determine the amount of aid attributable to development.

ENERGYTAX differs from a pure accounting model because the price of the coal or energy output is maintained internally at a level sufficient to keep the rate of return on discounted cash flow at 15 percent. Through a system of simultaneous equations, the model accounts for the effect that some taxes have on the tax base available for other taxes and on the price of the coal. This modification is important because, in some States, the price of the coal is a component of several tax bases. If the price were established without regard to the existing level of taxation, the price would be too low and revenues would be underestimated.

Development of ENERGYTAX required detailed analysis of each of the four States' tax and aid systems. For each State, the portions of the tax code that would affect the revenue available to State and local governments were identified and reduced to algorithms for use in the simulation. In addition, assessment practices, actual assessment ratios for different types of property, motor fuel consumption, and consumption of alcohol and tobacco had to be determined and included in the model.4/

Taxes identified and estimated for a mine or an energy conversion plant included State and local property taxes on land, equipment, and gross proceeds; State mineral taxes; special energy conversion taxes; State and local sales and use taxes; State unemployment taxes; and State corporate income taxes. State income taxes, sales taxes, alcohol and tobacco excise taxes, motor fuel taxes, motor vehicle registration fees, as well as State and local property taxes paid by individuals employed by the mine were calculated. In addition, estimates were made of changes in school aid payments and other intergovernmental transfers which depend on either the size of the local government or the revenues collected through a particular tax.

For this study, tax revenues were estimated for a normal operating year. ENERGYTAX is sufficiently general, however, to allow estimates to be made for any year from the beginning of development to the final closing of the mine. In this simulation, the firm's equipment is assumed to have depreciated to 75 percent of its original cost. When the firm's income taxes are computed, it is assumed that the mine is owned by a corporation which conducts business entirely

^{4/} For Montana, Morth Dakota, and Wyoming, these descriptions of the State tax system have been published separately. See Layton S. Thompson, The Taxation and Revenue Systems of State and Local Government in Montana as of 1976, Dept. Agr. Econ., Montana State Univ., Staff Paper 77-12, June 1977, 59 pp.; Layton S. Thompson, The Taxation and Revenue System of State and Local Governments in Wyoming, Dept. Agr. Econ., Montana State Univ., Staff Paper 77-13, July 1977, 58 pp.; and Stanley W. Voelker, The Taxation of State and Local Governments in North Dakota, N. Dakota State Univ., Agr. Econ. Rpt. 117, Dec. 1976, 63 pp.

within the borders of the State. If this assumption does not hold, corporate income tax payments will be smaller since the Stare corporate income tax will be based on the provisions of the Malti-State Tax Compact. It is also assumed that the mine or conversion plant is located outside the corporate limits of any city; consequently, no municipal property taxes are paid by the firm.

Estimates of State income and sales taxes paid by employees are based on the average taxes paid by individuals in each \$1,000-income class. The revenue from excise taxes and registration fees is estimated using the everage tax per adult resident. Local real property taxes are computed for three types of housing -- single-family detached, rental units, and mobile homes -- based on 1976 average assessed values in coal producing counties. The housing choice pattern is assumed to be the same as that found in an earlier study of impact ared housing.5/ The pattern found by the study -- 69 percent owner occupied, 16 percent rental, and 15 percent mobile homes -- is believed to be the best available estimate of the final distribution of workers among different types of housing.

The model does not allocate workers and worker families among different. cities, school districts, and counties. Instead, it is assumed that all new residents locate in the same school district, county, and municipality, or equivalently, that tax rates are identical in all jurisdictions of the same type. Also, it is assumed that all workers live within the corporate limits of the municipality. This assumption produces an estimate of the upper bound of the potential revenues available for the city. To the extent that individuals locate outside the city, the tax revenues and State aid will be reduced proportionately.

The change in State school aid, the most important of the intergovernmental revenues, is computed by applying the formula used by the State to a typical district in the coal region before development occurred and then reapplying the formula after the hypothesized development. The estimated number of new students in the elementary, junior high, and senior high age groups is again based on North Dakota experience. 6/ This model assumes that the average worker's family has 0.58 grade school students, 9.20 junior high school students, and 0.39 high school students. Total family size was assumed to average 3.37, with 87 percent of the workers married.

MODEL MINÉS

Three hypothetical strip mines were used in the simulations: a 2-millionton-per-year lignite mine, a 5-million-toń-per-year subbituminous mine, and a large-scale 9.2-million-ton-per-year subbituminous mine. The basic structure of each mine was taken from Bureau of Mines publications .7/. Cost data for all

^{5/} Arlen F. Leholm, Larry Leistritz, and James S. Wieland, Profile of North Dakota's Goal Mine and Electric Power Work Force, N. Dakota Agr. Exp. Sta., Agr. Econ. Rpt. 100, Aug. 1975, p. 5.

^{6/} Ibid., p. 26.

 $[\]overline{7}/\overline{A}$ short description of each model mine, the updated wage and investment cost schedules, and a complete citation to the original mines is provided in Appendix R.

three mines, however, had to be updated to reflect equipment prices and wage rates in early 1976. Each mine is similar to those currently operating in the region.

Few changes were made in the basic structure assumed for each mine in the Burgau of Mines reports. Minor changes were made in the equipment and manning tables to achieve comparability among the three sizes of model mines, however. The manning tables for the two smallest mines, for example, did not provide breakdowns of the maintenance and supervisory employees into occupational and professional categories. Other reports and unpublished survey materials were used to construct appropriate subsections of the manning tables so that frequency distributions could be made of the wage and salary earnings of employees. In some cases, this resulted in slight changes in total annual wage and salary costs of the mine.

The only substantive change made in the mine models was for the smallest mine. There, the estimated investment in farm machinery used for spoil-back reclamation was reduced from \$100,000 to approximately \$32,000 to more accurately reflect actual costs.

Capital investments and annual operating costs were adjusted to the price level of early 1976 by use of appropriate price indexes. Most indexes used were selected from those compiled by the U.S. Bureau of Labor Statistics and published monthly in Wholesale Prices and Price Indexes. Two of the Engineering News Record price index series were used to adjust the capital value of buildings, roads, and general construction work. Prices of large draglines and coal shovels, for which no published price index series seemed appropriate, were established arbitrarily after a review of published and unpublished price information.

Wages were adjusted upward to the level of early 1976, in accordance with provisions of the 1971 and 1974 Bituminous Wage Agreements with United Mine Workers, including the cost-of-living allowance provided by the 1974 contract.

White collar salaries were undated to maintain approximately the same percentage relationship to the union salary schedule. All operating costs including union welfare payments were updated to reflect any changes which may have occurred.

The model mines used in the simulation have several important differences in structure, some of which have noticeable impacts on the taxes they pay. The most important difference is that the 9.2-million-ton mine was developed originally as a model of a mine to fuel a coal conversion plant producing 250 million cubic feet of high BTU gas per day. The other mines were assumed to be export mines. As a result, the 9.2-million-ton model does not include any loading or preparation facilities, nor are any employees assigned to preparation or loading duties. If a preparation plant and loading facility were added to the 9.2-million-ton mine, the firm would have higher capital costs and operating expenses, as well as a considerable difference in the property tax base of the mine. As a result, total tax payments would increase.

Estimated State and local tax payments by the mines and their employees varied greatly depending on both the State and size of mine used in the simulation (table 1). Revenues would be greatest for a 9.2-million-ton mine in Montana (more than \$12.7 million per year) and smallest for a 2-million-ton lignite mine in South Dakota (\$335,000). Within each State, larger mines produced more revenue. However, differences among the States were large for each size of mine. The simulations indicate that all three mines would pay substantially greater taxes in Montana than in the other States. The total tax bill would be smallest in South Dakota, while North Dakota and Wyoming would collect similar amounts considerably greater than South Dakota but less than half that collected in Montana 8/

Total revenue is not the best measure of the mine's impact, however. More revealing are estimates of tax collections from the mine and its employees divided by the number of new residents brought in by the development. This report focuses on those new residents directly attributable to the mine's development. That group, comprised of the mine's employees and their immediate families, creates the need for additional services. A vital question is: are the taxes paid by the mine and its employees sufficient to cover additional community costs associated with the development?

Development will also be accompanied by a second group of new residents: those employed in service or nonbasic industries and their families. These simulations do not attempt to estimate potential government revenues from those individuals or their employers. While future versions of the ENERGYTAX model will allow for estimation of revenues from ancillary development, this report deals only with direct impacts.

Estimated revenue per new resident is considerably greater in Montana than for the other States (table 2). Both the 5- and 9.2-million-ton mines would generate more than \$16,000 in State and local revenue per new resident or more than \$55,000 per new family. No mine in the other States would bring in even half this much revenue per new resident. The model mines in North Dakota and Wyoming would produce more than \$5,400 per new resident or more than \$18,000 per new family, however. The South Dakota mines, of course, would yield consider ably less revenue, approximately \$1,400 per new resident or \$4,700 per new family.

Estimated taxes per ton of coal production vary from \$1.72 for the 5-million-ton mine in Yontana to \$.10 for the 9.2-million-ton mine in South Dakota (table 3). In all States but Montana, the 2-million-ton lignite mine would pay the largest tax per ton of production. In Montana (due to the special 20-per-cent severance tax on lignite, as opposed to a 30-percent tax on subbituminous coal), the 5-million-ton mine would pay the most tax. In all four States, the largest mine would pay the lowest tax per ton. With the exception of Montana,

^{8/} South Dakota has been included in the simulation even though no major coal development is expected. It can be thought of as a control State, indicating what the situation might be if no special coal taxes are enacted. South Dakota also has several taxes which are not used elsewhere in the region; a net proceeds tax and a property tax on the estimated mineral value of the land. Results from these taxes are useful for comparison purposes.

where a \$0.37-difference existed between the highest and lowest tax costs per ton, there was only a slight difference in the estimated taxes per ton, on the three sizes of mines.

Aggregate estimates of State and Ideal tax revenues tell only part of the story. Government services are provided by four major types of government: States, cities, counties, and school districts. Since each receives revenue from different sources, a significant financial problem for one or more governments could be hidden by a surplus at the other levels: The rest of this section discusses the revenues, including intergovernmental transfers, available to each type of government. Complete estimates of revenue by source for each level of government in each of the study States are given in Appendix C.

State Revenues

State governments would be major recipients of new tax revenues. Even then intergovernmental transfers are taken into account, States still retain more than half of all taxes paid by each mine and its employees. The State general fund, the fund into which those tax revenues not earmarked for specific purposes are deposited; would receive the single largest amount of new tax revenues in each State studied. Montana's general fund would receive the most and South Dakota's the least (table 4).

In each State, the special severance tax on minerals would produce the largest amount of new revenue (table 5). While both tax rates and the tax base vary greatly, all State mineral taxes produce considerable revenue. In fact, the 5-million-ton and 9.2-million-ton mines in Montana would each pay more than \$7 million in severance taxes, more than the total of all taxes on the mine and its employees in any other State.

On a per ton basis, the Montana Severance Tax and the Resources Indemnity of Trust Tax would range between \$1.07 and \$1.48 for the three mines, considerably more than North Dakota's \$.52 per ton and Wyoming's \$.22 to \$.30 per ton. South Dakota's mineral tax, a net production tax, might be thought of as a net income tax. This tax would be much less, ranging from \$.03 to \$.06 per ton.

The second largest source of State tax revenue in Montana and North Dakota would be the corporate income tax or corporate license fee. In these States,

from \$70,000 to \$412,000 would be collected depending on the size of the mine. These estimates, however, are valid only for mines owned by companies conducting all their business within the State. For multi-State firms, the situation is quite different. The net income for these firms is divided among States in accordance with a three-factor formula specified in the Multi-State Tax Compact on the allocation of income for taxation. 9/ For the Northern Great Plains. States, acceptance of the Multi-State Tax Compact effectively eliminates any taxation of the net income derived from sales of coal for export. Consequently, while both the Montana and North Dakota results include an estimate of corporate income taxes paid, this figure should be regarded as an upper bound. Export mines selling out of State are more likely to pay only the State's minimum tax.

Sales and use taxes are also a major source of revenue for State governments in North Dakota, South Dakota, and Wyoming. Wyoming also has an optional county, sales and use tax. Montana, however, does not levy a sales tax. While estimated State revenues are similar, differences in the items covered by the tax produce some variation among the States. For any given mine, South Dakota, which obtains the most revenue from the sales tax, would receive about one-third more revenue than would Wyoming. State sales tax revenues, while significant, are small compared to mineral tax revenues. Only in South Dakota would they be comparable in size.

Most sales tax revenues come from taxes paid by the mine on purchases of operating supplies and replacement equipment (table 6). These estimates pertain to a year when no major replacement equipment is purchased. Consequently, they should be considered estimates of the lower bound of potential revenues. In years when significant purchases of replacement equipment are made, sales tax revenues will be much greater. Sales and use taxes would also be collected on the initial complement of equipment installed at the mine. For the 9.2-million-ton mine, most of the original equipment cost of more than \$30 million would be subject to State-sales and use taxes. As a result, more than \$1.2 million would accrue to the State's treasury during the mine's construction and development stage.

Estimated State taxes paid by workers are relatively small (table 7). North Dakota and Montana would raise similar amounts—approximately 50 percent more than South Dakota and more than twice as much as Wyoming.

North Dakota, the State with the largest average tax per employee, has both a sales tax and an individual income tax. Montana, which collects almost as much revenue from individuals, has only an income tax. South Dakota and Wyoming have a sales tax but no income tax. Estimates of the other taxes paid by individuals directly to the State are shown in more detail in Appendix G.

For all but South Dakota, the taxes paid by the new employees fould be a small percentage of total State revenues accruing from the development—5 percent or less. In South Dakota, taxes on individuals would produce approximately 16 percent of the total State revenues from the new development. However, total State revenues would be much less in South Dakota than in the other three States.

^{9/} A more complete discussion of the Multi-State Tax Compact on the allocation of income may be found in Commerce Clearing House, State Tax Guide, Chicago, pp. 179-187.

Local Government Revenues

Local governments—school districts, counties, and cities—will be required to provide most of the additional public services required by a mine and its workers. Revenue necessary to finance this expansion of services must come almost entirely from either the local property tax or State aid to local governments.

There are large differences in the property tax and State aid systems among the four States in this study. And, while it is not our intent to review all those differences, certain special features that affect the taxes paid by mines should be noted. The most important is the definition of the local property base.

North Dakota exempts from property taxes practically all presonal property including mining machinery and equipment and the mine's gross proceeds. Only the value of the land and structures associated with the mine are included in the property tax base. Moreover, mineral values are not taken into account in determining the taxable value of the land. As a result, land used for mining is assessed at approximately the same amount per acre as is farmland in the area.

South Dakota includes mineral values in the assessed value of the land; personal property, including mining equipment and machinery, is also subject to tax. However, as in North Dakota, the gross proceeds of the mine are not subject to local property taxes.

Both Montana and Wyoming treat the gross proceeds of the mine as part of the local property tax base. The value of the machinery and other personal property of the mine is also included. While differences exist in the treatment of property and in the definition of gross proceeds used in these two States, their local tax bases are more nearly similar than those in North and South Dakota. As will be apparent later when gross proceeds are included as part of the property tax base, local governments receive considerably more revenue.

State intergovernmental aid systems also vary considerably. North Dakota; for example, places heavy reliance on State aid in financing elementary and secondary education. In Wyoming and South Dakota, on the other hand, the primary source of funds for local schools is the local property tax. Montana's school aid system is quite complex, but relies largely on local property tax revenues which in some instances may be redistributed through the aid system to other districts. These differences in the aid systems are important to any analysis of expected revenues from development. The differences are to important, in fact, that if State aid programs are ignored, quite different impressions about the ability of the school district to finance education are obtained.

The rest of this section presents estimates of the tax revenues and intergovernmental aid available to school districts, counties, and cities. These estimates help identify the levels of government and types of development where financial problems may occur.

School Districts

School district tax revenues in each State were computed by use of 1976 millage rates for districts in a major coal-producing county in that State. Although the school millage would probably decrease in those areas where the mine would add greatly to the assessed value of the district, all estimates were based on existing tax rates to provide a consistent basis for interstate comparisons.

wyoming school districts would receive an extremely large amount of additional revenue from the new mining development if millage rates remain constant, more than \$5,600 per pupil. School districts in Montana would receive almost \$1,400 per pupil, while districts in North and South Dakota would receive between \$750 and \$1,200 per pupil, depending on the State and the size of the mine (table 8).

The sources of new school revenue would vary considerably. In North Daketa, for example, less than a fourth of the total would come from local property taxes, while more than three-fourths would come from increased State aid. This contrasts markedly with Wyoming and South Dakota where less than 5 percent of the new revenue would come from the State. More detail about sources of revenue for school districts can be found in Appendix C. Two points should be noted. First, in Montana and Wyoming where the most local revenue would be generated, the property tax on gross proceeds is by far the largest source of new revenue. Second, in all States, taxes paid by new residents would provide only a small percentage of the total revenue required by the school district.

The estimates were based on the assumption that all workers reside in the school district where the mine is located. If that assumption does not hold, as is often the case, the district in which the mine is located will have even higher per pupil revenues. Other districts with new students but no mine will receive much less revenue per new student.

Per pupil revenue estimates in table 8 are based on the children of workers directly employed by the mine. To the extent that secondary or ancillary employment does not bring with it an equivalent increase in the tax base, new revenues per pupil will be smaller.

Counties

Estimated county revenues from new mine development varied tremendously among the four States. South Dakota counties would receive the least total revenue per new resident while Montana counties would receive the most (table 9). In North Dakota, more than 80 percent of total new revenues for the county would come from State aid, primarily from the portion of the severance tax revenues originating in the county returned by the State. But, in Wyoming and South Dakota, less than 20 percent of county revenues would come from State aid Wyoming counties would raise more revenue through property taxes than would counties in the other States and it is likely that county millage rates would be reduced as a result of development.

Cities

Because the mines are assumed to be located out de corporate limits, cities

would receive the least revenue of all units of local government. Tax revenues would come entirely from property taxes and special excise taxes paid by mine employees and their families. In all States but Wyoming, State aid is based either directly or indirectly on population or population change. Since the same family structure and housing choice patterns are assumed for all three model mines, only in Wyoming will per capita revenues for the cities differ depending on the mine size.

All new residents are essumed to locate within a single city. To the extent that individuals choose to live outside the city limits, locally collected revenues and State aid will decrease proportionately. However, in Wyoming where some State aid depends on local sales tax collections, total municipal revenue is not tied directly to the number of new residents living in the city.

Montana cities would receive the most revenue per new resident under these assumptions (\$74) and South Dakota cities the least (\$24) (table 10). In Wyoming, the largest part of the revenue would come from State aid and local shares of State-collected taxes. In the other three States, most of the revenue would come from taxes paid by mine employees.

The small amount of city revenue per new resident to be generated by mine employees highlights the importance of the tax revenues from the mine. It appears that any local government affected by the impacts of a new mine located outside its boundaries may be faced with serious financial problems. Possible exceptions are school districts in North Dakota and Montana where much of the operating revenue comes from State aid.

CONCLUSIONS

The simulations indicate that considerable tax revenue would be collected from a new mine and its employees in all States, even in South Dakota where no special coal taxes have been enacted. One important question from a policy point of view, however, is whether or not these revenues will be sufficient to cover the costs of the additional government services required by the development. This report presents no direct evidence on that question. Comparisons between the revenue estimates from the simulation and per capita expenditures of States and local governments in the four States studied do provide some insights, however.

Results from the revenue simulations and 1974 expenditures per capita for each level of local government in the four States are compared in table 11. Although there are many problems with using average per capita expenditures to project needs for future local government services, these comparisons do leave certain strong impressions.

First, it appears that total State and local tax revenues are more than sufficient to handle demands for government services by the mine and its employees in all States with the possible exception of South Dakota. In Montana, existing taxes would raise between \$11,700 and \$17,700 per new resident directly associated with the mine. In North Dakota and Wyoming tax revenues would be between \$5,400 and \$7,690 per new resident. Ancillary employment associated with the mine development probably will not bring with it anywhere near the same

^{2/} General expenditures of State and local governments are derived from data in U.S. Bureau of the 23 Census, Governmental Finances in 1974-75, GR 75, No. 5, tables 16 and 18.

amount of revenue per capita. Even so, it appears there will be sufficient revenue available to meet the new service needs of State and local governments.

All levels of government are not equally well off, however. State governments, and to a lesser extent the counties, would receive revenues in excess of what might be expected to be their needs. But, the cities appear to be facing a major financial problem. Cities would receive new revenues that are less than one-third average per capita expenditures in 1974-75. Unless the growth in the ancillary or nonbasic sector produces much greater for capita revenues than the mine-related growth, cities are likely to need additional funds.

Special coal-impact funds, administered at the State level, have been established in Montana, North Dakota, and Wyoming. These funds, potential source of aid for the cities, are financed by a fixed percentage of severance tax collections; large sums of money are available annually for projects in impacted areas. The administering agencies are authorized to make grants to local governments with coal-related development problems on a individual project basis. While there is no guarantee that any particular project or request will receive funding, the programs offer some hope to cities and other impacted governmental units. Without this additional aid, however, it appears that either taxes will have to increase or service levels will decline when new mines are developed.

For local schools, probably the level of government of greatest concern, the evidence is unclear except in Wyoming. There it is apparent that the additional revenues will exceed the needs of the school district and that a millage reduction for the entire district will occur. This ignores, of course, the problems of districts that do not contain mines but receive some new residents. Those districts are likely to have financial difficulties because the portion of school revenue which comes from taxes on the individual is quite small.

In other States, more evidence is needed. Although total revenue per new resident for schools is slightly greater than the average expenditure per capita on education in the State, the difference is not great. Moreover, the expenditure figures are for 1974-75 and the revenue estimates from 1976. Consequently, inflation may have further reduced the difference. And, to the extent that the nonbasic sector does not have as much property value per child as the mining sector, the total picture may be even less optimistic. Another problem is that the appropriate cost estimate depends on the capacity and the extent of utilization of the existing school facilities in the particular district under consideration. In districts where class sizes are small and the new students can be accomodated without adding teachers or classrooms, the cost of the additional students will be less than the average for the State. In other situations, however, where the local system is at or near capacity and new physical plant and teachers will have to be added to take care of the increased enrollment, the costs may be considerably above the State average. Without good cost estimates, it is impossible to say whether individual school districts would receive sufficient funds from the new development.

The results of this study, while providing considerable insight into the fiscal-impact issue, leave a number of issues unresolved. There is, for example, a need to extend the model to include the secondary or ancillary economic

growth that accompanies a mine. From the mine owner's point of view, there is no reason that the taxes paid by the mine should be expected to pay for the services demanded by other firms and their employees. But, the planner or the local official may consider it important to know what the situation will be when all the development likely to occur is taken into account. Better information on the costs of expanding State and local government services is also required.

Also, no direct evidence is given on the front-end financing problem. Until the new mine actually comes into full production, the immediate need for new services may outstrip a locality's ability to finance them. Since it can take up to 3 years to ready a coal mine for operation, communities will face more than a temporagy financial imbalance. Partial evidence on the extent of that deficit can be obtained from Appendix C. Approximations of the revenue available during the construction period can be found by deducting all net income saxes, severance taxes, and property taxes paid by the mine from the existing totals. In Wyoming, for example, the 9.2-million-ton mine would pay only about \$343,000 per year in State and local taxes instead of the \$4.4 mil-Lion estimate for desperating year. Since many State constitutions set limits on local millages and restrict the use of bonding to the financing of capital facilities, the front-end impacts can be difficult to handle. During the construction period, the fiscal deficit for a community is likely to be large and some way of spreading that impact over time is desired. Again, the coal impact funds with their combination of loans and grants car play an important role.

It appears that under the 1976 tax structure, new residents directly associated with the development of a line need not create major financial problems for State and local governments in the study area. While some redistribution of funds may be required both through time and among levels of government—through an expanded stem of State aid to the cities, for example—sufficient revenues will be generated by existing taxes.

State and local taxes are too high from a national point of view. No study can provide a precise answer to that question. Although the revenues appear to be sufficient to cover the direct public sector costs associated with providing services for new employees and their families, those are only part of that costs that must be considered.

Coal development will also inflict other, less easily and costs on residents of the region-increases in pollution and force changes in lifestyle. Residents of the argument of the compensated for these costs, and industry needs to recognize their development planning. While it is impossible for mine owners to asate each resident individually, such compensation can be done throughout and public expenditure system. By taxing in excess of the costs and at least partially compensate the region's the changes imposed on them. While this report provides some of the relative size of the compensation, we have no evil the changes in the compensation of the relative size of the compensation of the compensation of the relative size of the compensation of the relative size of the compensation of the relative size of the compensation of the compensation of the relative size of the compens

APPENDIX A: DATA REQUIREMENTS FOR THE ENERGYTAX MODEL

Each State model has slightly different data requirements due to differences in State tax structures. However, input data requirements are similar for all States. Each model requires user-supplied estimates of the number of acresto be mined or held under contract during the year to be simulated, the assessed value per acre of that land, the expected number of tons to be mined annually, and the number of individuals employed during the year to be simulated. The model also requires data on the earnings of the employees. For the ENERGYTAX model, that information is entered as a vector with each element containing the number of workers whose earnings fall in a particular \$1,000 range. Total operating costs and the dollar return net of depreciation necessary to produce the prescribed rate of return on discounted cash flow are also required for each simulation.

In the sales tax States--North Dakota, South Dakota, and Wyoming--estimates of equipment purchases and purchases of operating supplies are necessary. Since the coverage of the sales tax varies among States, data on major purchases must be provided separately. Fuel, Lubricants, power, tires, and spare parts all may be subject to different tax treatment in different States.

The property tax treatment of the machinery and structures associated with the mine also vary, changing the data requirements of the State models. In North Dakota, only land and structures are taxable, all other personal property is exempt from the property tax. A separate estimate of the value of structures is required for the model for North Dakota. In Montana, equipment classified as motor vehicles is taxed differently than other mining machinery. As a result, separate estimates of motor vehicles and other equipment are necessary. In addition, an estimate of the expected inventory of coal stored at the mine is necessary for Montana.

The user must also supply the millage rates to be used for local preperty taxes in each State. In Montana, the user is also required to indicate whether the 30-percent or 20-percent severance tax rate should be used. In Wyoming, if the county has chosen to collect a local sales tax, the local sales tax rate must also be indicated.

APPENDIX B: CHARACTERISTICS OF THE MODEL, MINES

This appendix provides descriptions of the three model mines, including the various assumptions made regarding their operations and tabulations of estimates of both capital requirements and annual operating costs.

The 2-Million-Ton-Per-Year Lignite Mine

Cost estimates for this model were developed by Skelly and Loy Engineers-Consultants as part of a study for the U.S. Bureau of Mines. 10/ The consulting firm assumed price levels of late 1974 and the wage rates established by the UMW Bituminous Wage Agreement of 1971. For purposes of the current study, these cost estimates were adjusted to price levels prevailing in January 1976 by use of various price indexes. Also, wage rates were assumed to be those established by the UMW Bituminous Wage Agreement of 1974, including the cost-of-living allowance.

This multipit operation is fairly representative of several medium to large lignite strip mines in western North Dakota. Practically all production is exported for electrical power production. The overburden, consisting of unconsolidated clay and scoria, ranges from 10 to 90 feet in thickness, with an average of about 60 feet. Three seams are being mined, which average 6, 12, and 4 feet in thickness, respectively, separated by 5-foot partings.

The topsoil, removed by pan scrapers, is stockpiled and seeded down temporarily to prevent erosion. Because of the nature of the overburden, blasting is not necessary prior to removal. Two relatively small electric-powered draglines — 12— and 17-cubic-yard buckets — are used to remove the overburden. The draglines uncover the top seam and then move to another pit. After the top coal seam is extracted, a dragline returns to remove the parting. Both overburden and partings are placed directly into the adjoining cut from which all three coal seams had been removed previously. Some of the scoria is saved for haul-road construction.

A small amount of ANFO (an explosive) is used to blast the lignite seams. Three small electric coal shovels and a front-end loader are used to load the lignite into 65-ton coal haulers for transfer to the coal-preparation plant and tipple. The average haul is about 2 miles to the primary hopper. The lignite goes through primary and secondary crushers before being loaded onto unit trains for transport to electric power plants. It is assumed that the mining company owns the preparation plant and loading facilities.

The disturbed land is regraded to approximately the original contour by use of bulldozers. Topsoil is replaced by use of pan scrapers. Approved mixtures of grasses and legumes are seeded by employees of the mining company. Under the various assumptions made for this mine, production of 2 million tons per year would require strip mining and reclaiming an annual average of 71 acres.

^{10/} Skelly and Loy Engineers-Consultants. Economic Engineering Analysis of U.S. Surface Coal Mines and Effective Land Reclamation, U.S. Bureau of Mines Contract Rpt. S0241049, Feb. 1975, pp. 9-175 to 9-185.

A total of 71 people are employed at the mine site, 53 of whom are union-wage employees and 18 are salaried professional and administrative people. The dragline operators and oilers are employed in three shifts per day, 7 days per week (340 days per year). Some of the drillers and scraper operators are employed in two shifts per day, 280 days per year, but most of the wage employees are on a one shift per day basis, 280 days per year.

The 5-Million-Ton-Per-Year Subbituminous Mine

The cost estimates for this model were developed by Skelly and Loy Engineers—consultants in the same study noted previously for the 2-million-ton-per-year lignite mine. 11/ These estimates were also adjusted to price levels of January 1976 by use of various price indexes for purposes of the current study.

This model is fairly typical of the medium-sized subbituminous strip mines in eastern Montana and northeastern Wyoming. The coal seam is nearly level, with an average thickness of 52 feet. Because of the properties of the coal. (heat value of 9,600 Btu's per pound, ash content of 3.7 percent, and sulfur content of only 0.33 percent), it is in great demand at Midwest electric generating plants for blending with high sulfur Midwest coal. The overburden, which ranges up to 150 feet in thickness with an average of about 65 feet, consists of sandy alluvial till, interbedded with clay, sandstone, and shale.

Topsoil is removed and stockpiled by use of pan scrapers. Since the overburden is fairly well consolidated, it is blasted with ANFO prior to removal. Blast holes are 12½ inches in diameter on 30-foot spacings. The overburden is removed by an electric-powered dragline, equipped with a 41-cubic-yard bucket, and placed in the adjacent, previously mined cut. The coal is blasted with ANFO (6-inch holes on 16-foot centers). The coal is loaded with two electric coal shovels, equipped with 26-yard dippers, into 70-ton bottom dump coal haulers. Because of seam thickness, benching into two 26-foot lifts is required. A front-end loader is used for cleanup and auxiliary loading.

The coal is crushed at the preparation plant to a top size of 2 inches. The plant has a capacity of 2,000 tons per hour. Storage is in two 13,000-ton silos. The coal is flood-loaded onto 100-car unit trains for shipment to Midwest utility plants. The coal is electronically weighed and automatically sampled during loading. A 10,000-ton train can be loaded in about 2 hours.

The disturbed land is regraded to smooth contours by large bulldozers. The topsoil is feplaced by use of pan scrapers and seeded down with approved grasses and legumes by use of a hydroseeder. This implement applies seed and fertilizer as a slurry and lays down a straw mulch in one operation.

A high coal-recovery rate of at least 90 percent can be assumed because of the thickness of the coal seam. At this rate, the estimated coal yield would average 81,900 tons per acre. An annual production of 5 million tons would mean an average of 61 acres to be mined and reclaimed each year.

A total of 157 people are employed at the mine site, 117 of whom are union wage employees and 40 are professional and administrative personnel. The dragline operators and oilers are organized into three shifts per day, 7 days per week (345 days per year). Most of the other miners are on a two-shift per day basis, 6 days per week (295 days per year), although a few are on the basis of one-shift per day, 240 days per year. Average employee earnings are relatively high because so much overtime is worked.

^{11/} Skelly and Loy Engineers-Consultants, op. cit., pp. 9-164 to 9-174.

The 9.2-million-Ton-Per-Year Subbituminous Mine

This model was one of three prepared originally in 1974 by the U.S. Bureau of Mines to illustrate what would be required to provide feedstocks for a minemouth, coal gasification plant with a daily capacity of 250 million cubic feet of pipeline quality gas. 12/ Costs of materials and equipment were based on

^{12/} Sidney Katell and E.L. Hemingway. <u>Basic Estimated Capital Investments and Operating Costs for Coal Strip Mines</u>, U.S. Bur. Mines, Inf. Circ. 8661, Wash., D.C., 1974.

1973 and early 1974 indexes. Wages and union welfare payments were assumed to be as of May 12, 1974, under the Bituminous Wage Agreement of 1971. Subsequently, the cost estimates for materials and equipment were adjusted for inflation by use of 1975 indexes. Wages and union welfare payments were changed in accordance with the Bituminous Wage Agreement of 1974. 13/ The current study adjusted these cost estimates to price levels of January 1976 by use of appropriate price indexes.

This large multipit mine is assumed to be located in the Powder River Basin of either Montana or Wyoming. Only one mine as large as this model is now being operated in this region, but several export mines, now being developed, will be as large or larger.

The coal is of subbituminous rank, with 9,600 Btu's per pound and low ash and sulfur content. The coal seam is fairly level and averages 25 feet in thickness, with an average of 70 feet of overburden. Topsoil is removed and stockpiled by use of wheel tractor scrapers. Both overburden and coal are blasted with ANFO prior to removal. The two overburden drills are expensive, electric-powered pieces of equipment, capable of drilling holes of 9-inch to 15-inch diameter. Two smaller, lighter drills are used for drilling the coal. The blasted overburden is removed by two large electric-powered draglines and placed directly in the adjoining, mined-out cuts. The drills and draglines are backed up by bulldozers and wheel tractor scrapers.

Two electric-powered coal shovels, equipped with 15-cubic-yard dippers, load the coal into bottom-dump, 120-ton coal haulers. A 15-cubic-yard front-end loader works with each shovel for cleanup and auxiliary loading. The run-of-the-mine coal is hauled directly to stockpiles at the gasification plant. without any preparation. Haul-roads are maintained by graders and bulldozers. Sprinkling trucks are used to keep down the dust.

At an assumed recovery rate of 90 percent, coal production will average 39,375 tons per acre. To produce 9.2 million tons per year would require an annual average of 293 acres for both mining and reclamation. Bulldozers are used to regrade the spoil banks to a gently rolling contour. Topsoil is replaced by use of wheel tractor scrapers. The rest of the reclamation work (seeding, fertilization, and mulching) is contracted out.

The work force at the mine site totals 213, of whom 189 are union wage employees and 24 are professional and administrative personnel. The dragline operators and oilers are assumed to work in three shifts per day, 7 days per week; (345 days per year). Most of other mining and maintenance employees work in two shifts per day, 5 days per week (240 days per year).

Capitel Investment and Operating Costs for Coal Strip Mines (Revision of Inf. Circ. 8661), U.S. Bur. Mines, Inf. Circ. 8707, Wash., D.C., 1976.
